Explosive-strength training improves 5-km running time by improving running economy and muscle power

LEENA PAAVOLAINEN,1 KEIJO HÄKKINEN,2 ISMO HÄMALÄINEN,1 ARI NUMMELA,1 AND HEIKKI RUSKO1

1KIHU-Research Institute for Olympic Sports; and 2Neuromuscular Research Center and Department of Biology of Physical Activity, University of Jyväskylä, SF-40700 Jyväskylä, Finland

Paaavolainen, Leena, Keijo Hääkinen, Ismo Hämäläinen, Ari Nummela, and Heikki Rusko. Explosive-strength training improves 5-km running time by improving running economy and muscle power. J. Appl. Physiol. 86(5): 1527–1533, 1999.—To investigate the effects of simultaneous explosive-strength and endurance training on physical performance characteristics, 10 experimental (E) and 8 control (C) endurance athletes trained for 9 wk. The total training volume was kept the same in both groups, but 32% of training in E and 3% in C was replaced by explosive-type strength training. A 5-km time trial (5K), running economy (RE), maximal 20-m speed (V̇O2max), and 5-jump (5J) tests were measured on a track. Maximal anaerobic (MART) and aerobic treadmill running tests were used to determine maximal velocity in the MART (V̇O2max) and maximal oxygen uptake (V̇O2max). The 5K time, RE, and V̇O2max improved (P < 0.05) in E, but no changes were observed in C. V̇O2max and 5J increased in E (P < 0.01) and decreased in C (P < 0.05). V̇O2max increased in C (P < 0.05), but no changes were observed in E. In the pooled data, the changes in the 5K velocity during 9 wk of training correlated (P < 0.05) with the changes in RE (r = 0.54) and V̇O2max (r = 0.55). In conclusion, the present simultaneous explosive-strength and endurance training improved the 5K time in well-trained endurance athletes without changes in their V̇O2max. This improvement was due to improved neuromuscular characteristics that were transferred into improved V̇O2max and running economy.

distance running; neuromuscular characteristics; maximal oxygen uptake; maximal anaerobic treadmill running; endurance athletes

ENDURANCE TRAINING ENHANCES the function of the cardiorespiratory system and the oxidative capacity and glycogen stores of the muscles (e.g., Refs. 1, 20). Heavy-resistance strength training results in neural and muscle hypertrophic adaptations that are known to be primarily responsible for improved strength performance (e.g., Refs. 13, 15). A specific type of strength training, explosive-strength training, may lead to specific neural adaptations, such as the increased rate of activation of the motor units, whereas muscle hypertrophy remains much smaller than during typical heavy-resistance strength training (13, 15, 39).

It has been suggested that simultaneous training for both strength and endurance may be associated with limited strength development during the later weeks of training, whereas the development of maximal O2 uptake (V̇O2max) is not influenced as much (e.g., Refs. 10, 16, 18, 22). These observations are mainly based on experiments in which heavy-resistance strength training has predominated and the subjects have been previously untrained. However, proper strength training used simultaneously with endurance training may also result in some improvements in strength performance of endurance athletes (22, 35).

Many endurance-sport events require high aerobic power, and V̇O2max is a good predictor of endurance performance in untrained subjects. However, some other factors, such as running economy (RE) or peak treadmill running performance, may be better predictors of endurance performance than V̇O2max in a homogeneous group of well-trained endurance athletes (e.g., Refs. 4, 6, 30, 32). The endurance athletes must also be able to maintain a relatively high velocity over the course of a race. This emphasizes the role of neuromuscular characteristics related to voluntary and reflex neural activation, muscle force and elasticity, and running mechanics (13) as well as the role of anaerobic characteristics in elite endurance athletes. Bulbulian et al. (5) and Houmard et al. (21) have shown that anaerobic characteristics can differentiate well-trained endurance athletes according to their distance running performance. Heavy-resistance strength training has improved the endurance performance of previously untrained subjects (e.g., Refs. 17, 28, 29) or RE of female distance runners (24) without changes in V̇O2max suggesting that neuromuscular characteristics may also be important for endurance performance. Consequently, Noakes (31) and Green and Patla (12) have suggested that V̇O2max and endurance performance may be limited not only by central factors related to O2 uptake (V̇O2) but also by so-called “muscle power” factors affected by an interaction of neuromuscular and anaerobic characteristics.

In the present study, muscle power is defined as an ability of the neuromuscular system to produce power during maximal exercise when glycolytic and/or oxidative energy production are high and muscle contractility may be limited. Peak velocity (V̇O2max) reached during the V̇O2max treadmill running test has been shown to be a good indicator of endurance performance in middle- and long-distance running events (e.g., Refs. 4, 31, 32). Noakes (31) has suggested that V̇O2max could also be used as a measure of the muscle power factor in endurance runners. However, in addition to the neuromuscular and anaerobic characteristics, the aerobic processes are also strongly involved in V̇O2max (e.g., Ref.
19). Recently, it has been suggested that peak velocity in the maximal anaerobic running test ($V_{\text{MART}}$), which is influenced both by the anaerobic power and capacity and by the neuromuscular characteristics without the influence of VO$_2$max could be used as a measure of muscle power (38).

The purpose of this study was to investigate the effects of simultaneous explosive-strength and endurance training on 5-km running performance, aerobic power, RE, selected neuromuscular characteristics, and muscle power in well-trained endurance athletes.

**METHODS**

Subjects. The experimental (E) group consisted of 12 and the control (C) group of 10 elite male cross-country runners (orienteers), and the groups were matched with regard to VO$_2$max and 5-km time trial. During the study period, two E and two C athletes were excluded because of injuries or illness. The physical characteristics of both groups before and after the experimental period are presented in Table 1. The percentage of body fat was estimated from the thickness of four skinfolds (triceps brachii, biceps brachii, subscapula, and suprailium) (11). The right calf and thigh girths were measured with a tape applied around the relaxed muscles. This study was approved by the Ethics Committee of the University of Jyväskylä, Jyväskylä, Finland.

Training. The experimental training period lasted for 9 wk and was carried out after the competition season. The total training volume was the same in both E and C groups (8.4 ± 1.7 h and 9 ± 2 times/wk and 9.2 ± 1.9 h and 8 ± 2 times/wk, respectively), but 32% of training hours in the E group and 3% in the C group were replaced by sport-specific explosive-strength training. The rest of the training in both groups was endurance training and circuit training (Fig. 1). Explosive-strength training sessions lasted for 15–90 min and consisted of various sprints (5–10)·(20–100 m) and jumping exercises [alternative jumps, bilateral countermovement, drop and hurdle jumps, and 1-legged, 5-jump (5J) tests] without additional weight or with the barbel on the shoulders and leg-press and knee extensor-flexor exercises with low loads but high or maximal movement velocities (30–200 contractions/training session and 5–20 repetitions/set). The load of the exercises ranged between 0 and 40% of the one-repetition maximum. Endurance training of both groups consisted of cross-country or road running for 0.5–2.0 h at the intensity below (84%) or above (16%) the individual lactate threshold (LT). Circuit training was similar in both groups; the C group trained more often than did the E group, and training consisted of specific abdominal and leg exercises with dozens of repetitions at slow movement velocity and without any external load.

Measurements. The E and C groups were examined before training and after 3, 6, and 9 wk of training, except for the 5-km time trial (5K), which was only performed before and after 6 and 9 wk of training. The schedule of two measurement days is seen in Table 2. On the first day, after the anthropometric measurements and a warm-up, the maximal isometric force of the leg extensor muscles was measured on an electromechanical dynamometer (15). Three to five maximal isometric contractions were performed at the knee and hip angles of 110°. The force in each contraction was recorded by a microcomputer (Toshiba T3200 SX) by using an AT Codas analog-to-digital converter card (Dataq Instruments). VO$_2$max and LT were determined during the maximal aerobic power test on a treadmill. The initial velocity and inclination were 2.22 m/s and 1°, respectively. The velocity was increased by 0.28 m/s after every 3-min stage until the velocity of 4.75 m/s was reached, except for two velocity increases of 0.56 m/s in the middle of the test. After 4.75 m/s was reached, the velocity was kept constant but the inclination was increased by 1° every minute until exhaustion. Fingertip blood samples were taken after each velocity to determine blood lactate concentrations by an enzymatic-electrode method (EBIO 6666, Eppendorf-Netheler-Hinz). Ventilation and VO$_2$ for every 30-s period were measured by using a portable telemetric O$_2$ analyzer (Cosmed K2) (7). The LT as VO$_2$ (ml·kg$^{-1}$·min$^{-1}$) was determined at the point at which blood lactate concentration distinctly increased from its baseline of 1–2 mmol/l (2, 23) and was verified by using respiratory data (2, 40). VO$_2$max was taken as the highest mean of two consecutive 30-s VO$_2$ measurements (ml·kg$^{-1}$·min$^{-1}$). Because the inclination of the treadmill was increased and the velocity was kept constant during the last stages of the test, peak treadmill running performance was calculated not as the peak velocity ($V_{\text{O2max}}$) but as the O$_2$ demand of running during the last minute before exhaustion.

(\(V_{O2max}\)) is calculated by using the formula of the American College of Sports Medicine (1991).

\[
\dot{V}O_2 = 0.2 \cdot v (\text{m/min}) + 0.9 \cdot \text{grade (frac)} \cdot v (\text{m/min}) + 3.5
\]

where \(v\) is the speed of the treadmill, grade is the slope of the treadmill expressed as the tangent of the treadmill angle with the horizontal, and frac is fraction.

After 20 min of recovery the subjects performed a MART (37), which consisted of a series of 20-s runs on a treadmill with a 100-s recovery between the runs. A 5-s acceleration phase was not included in the running time. The first run was performed at a velocity of 3.71 m/s and a grade of 4°. Thereafter, the velocity of the treadmill was increased by 0.35 m/s for each consecutive run until exhaustion. Exhaustion in the MART was determined as the time when the subject could no longer run at the speed of the treadmill. \(V_{MART}\) was determined from the velocity of the last completed 20-s run and from the exhaustion time of the following faster run (37).

On the second day, the subjects performed four tests on a 200-m indoor track: a maximal 20-m speed \(V_{20m}\) test, a SJ, a submaximal RE test, and a 5K (Table 2). After a 20-min warm-up the subjects ran three times the maximal 20-m run with a running start of 30 m and performed the SJ test three to five times. The 20-m running times were measured by two photocell gates (Newtest, Oulu, Finland) connected to an electronic timer, and the \(V_{20m}\) was recorded. The SJ was started from a standing position, and the subjects tried to cover the longest distance by performing a series of five forward jumps with alternative left- and right-leg contacts. The distance of the SJ was measured with a tape.

Ten minutes after the \(V_{20m}\) and SJ tests, the subjects performed the RE test (2-5 min). The velocity of the runs was guided by a lamp speed-control system ("light rabbit," Protom, Naakka, Finland). \(V_{O2}\) during the runs was measured by using the portable telemetric \(O_2\) analyzer (Cosmed K2) and track RE was calculated as a steady-state \(V_{O2}\) (ml·kg\(^{-1}\)·min\(^{-1}\)) during the last minute of running at the 3.67 and 4.17 m/s velocities.

Ten minutes after the RE test, the subjects performed the 5K on the 200-m indoor track. The mean velocity of the 5K (\(V_{5K}\)) was calculated. At the beginning of the 5K and after running 2.5 and 4 km, all subjects ran one 200-m constant-velocity lap (CVL) at the 4.55 m/s velocity through the photocell gates. The velocity of the CVLs was guided by the lamp speed-control system. The CVLs were run over a special 9.4-m-long force-platform system, which consisted of five two- and three three-dimensional force plates (0.9/1.0 m, TR Testi, natural frequency in the vertical direction 170 Hz) and one Kistler three-dimensional force platform (0.9/0.9 m, 400 Hz, Honeycomb, Kistler, Switzerland) connected in series and covered with a tartan mat. Each force plate registered both vertical (\(F_z\)) and horizontal (\(F_x\)) components of the ground reaction force. \(F_z, F_x,\) and contact times (CT) were recorded by a microcomputer (Toshiba T3200 SX) by using an AT Codas analog-to-digital converter card (Dataq Instruments) with a sampling frequency of 500 Hz. Stride rates (SR) were calculated by using CTs and flight times (FT) [1/(CT + FT)] and stride lengths by using velocity and SRs (VSR). Each run included four to six contacts on the force-platform system. The horizontal force-time curve was used to separate the CT and \(F_z\) and \(F_x\) force components into the braking and the propulsion phases. The integrals of both force-time curves were calculated and divided by the respective time period to obtain the average force for the whole contact phase and for the braking and propulsion phases separately.

Statistical methods. Means and SDs were calculated by standard methods, and Pearson correlation coefficients were used to evaluate the relationships among the variables. The significance of changes between the test values and differences within the E and C groups were tested by multiple analysis of variance for repeated measures (MANOVA). If a significant \(F\) value was observed, Student’s t-test was used to identify differences within groups. Because of slight initial group differences, analysis of covariance by using the pretest values as the covariate was employed to determine significant differences between the posttest adjusted means in the E group and those in the C group.

RESULTS

The 5K time did not differ significantly between the groups before the experiment, but, according to analysis of covariance, E and C group 5K times were different
**DISCUSSION**

It has been shown (36) that adult endurance athletes who continue their endurance training for several years seem to reach a more or less apparent ceiling of V\textsubscript{O\textsubscript{2max}} and endurance performance. Some previous training studies (17, 28, 29) have found that strength

training may lead to improved endurance performance in previously untrained subjects. The present study showed that simultaneous sport-specific explosive-strength and endurance training may also improve 5-km running performance (and peak treadmill running performance, i.e., $V_{20m,5J}$) of well-trained male endurance athletes. The mechanism of this improvement is suggested to be related to an explosive-strength-training effect: neuromuscular characteristics measured by $V_{20m,5J}$, and CTs of CVLs were improved and transferred into improved muscle power ($V_{\text{MART}}$) and RE.

The present 9-wk explosive-type strength training resulted in considerable improvements in selected neuromuscular characteristics, although a large volume of endurance training was performed concomitantly. This was demonstrated by the significant improvements in $V_{20m}$ and $5J$, and by the shortening of the CTs during the CVLs of the 5K, whereas no changes were observed in the ground reaction forces or maximal force of the trained muscles. These results support our previous findings (35) that in well-trained endurance athletes training-induced improvements in neuromuscular characteristics may not be fully inhibited by simultaneous explosive-strength and endurance training.

It has been suggested (3, 26) that the nervous system plays an important role in regulating muscle stiffness and utilization of muscle elasticity during stretch-shortening cycle exercises, in which high contraction velocities are used. The present increases in neuromuscular performance characteristics might primarily be due to neural adaptations, although no electromyographic measurements in the muscles were done to support this suggestion. Although the loads used in the present explosive-strength training were low, the muscles are known to be highly activated because of the maximal movement velocity utilized (13). It has been shown that this type of explosive-strength training results in increases in the amount of neural input to the muscles observable during rapid dynamic and isometric actions (e.g., Refs. 14, 15), suggesting that the increase in net excitation of motoneurons could result from increased excitatory input, reduced inhibitory input, or both (39). It is likely that training-induced alterations in neural control during stretch-shortening cycle exercises such as running and jumping may take place in both voluntary activation and inhibitory and/or facilitatory reflexes (13, 25, 26, 39). Although neural activation of the trained muscles during explosive-type strength training is very high, the time of this activation during each single muscle action is usually so short that training-induced muscular hypertrophy and maximal strength development take place to a drastically smaller degree than during typical heavy-resistance training (13). Consequently, it has been suggested (35) that, during relatively short training periods of some weeks, the improvements in sprinting and/or explosive-force-production capacity, especially in endurance athletes, might primarily come from neural adaptations without observable muscle hypertrophy (see also Refs.
